13. ABSTRACT (maximum 200 words)

In this thesis, we present two lossless compression approaches. Our Rotational Tree Approach (RTA) is based upon mathematics developed by Fredricksen. RTA uses the rotations associated with binary necklace classes to disperse source bit strings to a forest of Huffman encoding trees. Our Indexed Tree Approach (ITA) also uses a Huffman forest, but disperses bit strings via a simpler mechanism based upon the first few bits of each string. For text compression, we find RTA to be competitive with standard Huffman encoding while ITA is generally superior by a small margin of $1\% - 3\%$. Both approaches owe their (limited) success to decreased modeling overhead as compared to standard Huffman encoding. Compression results against the Canterbury Corpus test suit and complete Java implementation code are included as appendices.

ABSTRACT

In this thesis, we present two lossless compression approaches. Our Rotational Tree Approach (RTA) is based upon mathematics developed by Fredricksen. RTA uses the rotations associated with binary necklace classes to disperse source bit strings to a forest of Huffman encoding trees. Our Indexed Tree Approach (ITA) also uses a Huffman forest, but disperses bit strings via a simpler mechanism based upon the first few bits of each string. For text compression, we find RTA to be competitive with standard Huffman encoding while ITA is generally superior by a small margin of $1\% - 3\%$. Both approaches owe their (limited) success to decreased modeling overhead as compared to standard Huffman encoding. Compression results against the Canterbury Corpus test suit and complete Java implementation code are included as appendices.

ACKNOWLEDGMENTS

This thesis would not have been completed without the tireless efforts and tremendous production of Jason P. Marchant. He currently attends California Polytechnic State University, in San Luis Obispo, in pursuit of a Master of Science in Computer Science. Jason spent countless hours writing Java code and researching data compression techniques. Without his exhaustive efforts, we would not have been able to analyze the data and derive the conclusions that we present in order to complete our thesis.

THIS PAGE INTENTIONALLY LEFT BLANK

I.   INTRODUCTION

A search for the string 'Huffman Encoding' in the academic science and engineering database *Ei Compendex Web* [1] yields the following results:

- 1970's database - 27 papers found

- 1980's database - 61 papers found

- 1990's database - 305 papers found

Clearly, despite the passing of nearly 50 years since D.A. Huffman's [2] landmark work on lossless compression, new uses are still being found for his ideas at ever increasing rates. The purpose of this paper is to present two previously untried approaches to lossless compression both of which involve the notion of multiple Huffman encoding trees.

·Our Rotational Tree Approach (RTA) is based upon mathematics developed by Fredricksen [3, 4]. RTA uses the rotations associated with binary necklace classes to disperse source bit strings to a forest of Huffman encoding trees. Our Indexed Tree Approach (ITA) also uses a Huffman forest, but disperses bit strings via a simpler mechanism based upon the first few bits of each string. For text compression, we find RTA to be very competitive with standard Huffman encoding while ITA is generally superior by a margin of 1% – 3%.

II.   COMPRESSION FOUNDATIONS

A.   COMPRESSING / DECOMPRESSING

In general, lossless data compression consists of reading a stream of symbols from file A, replacing each symbol with some (hopefully shorter) binary code, and writing the new codes to some file B. File B is now a compressed version of file A (or expanded, if the method was ineffective). The decompression process is the inverse. The codes stored in file B are read, converted to the original symbols, and written to some new file C. Upon successful completion of a lossless compression / decompression cycle, file C is identical to file A.

B.   LOSSY VS. LOSSLESS

Data compression techniques can be divided into two broad categories – lossy and lossless. As the name implies, lossy compression techniques sacrifice some of the information content of the source file. Lossless compression techniques, on the other hand, preserve all the information content of the original file. Lossless techniques demand that the uncompressed file be bit for bit identical with the original source file.

Lossy compression is often used on files containing digitized voice or image data. Lossy compression makes sense in these settings since digital audio and video data files are always truncations of their original analog sources. Since one doesn't have all the data to begin with, it is often acceptable to sacrifice a bit more for the sake of compression (so long as the loss is not readily noticeable to the end user). Popular lossy compression schemes include JPEG (for images), MPEG (for video), and MP3 (for

3

audio). Lossy compression, while both useful and interesting, is not the subject of this thesis and will not be discussed further.

Lossless methods are used to compress documents, database records, executable files, and any other form of data that must be reproduced exactly. The two compression algorithms discussed in this paper are lossless.

C.   INFORMATION THEORY

The theory of information developed by Claude Shannon [5] in the 1940's concerns the study of the storage, processing, and transmission of information. Information Theory provides an objective mathematical way of measuring the *information content* of a particular symbol (within a given message) and of the whole message. Information content is referred to as *entropy*, and is generally measured in bits. The entropy E of an input symbol i can be calculated using

$$E(i) = \log_2(1 \ / \ p(i)),$$

Equation 1

where p(i) is the probability of i occurring in the message. The entropy H of an entire message (typically a file) is then the sum of the entropies of all the individual symbols in the message, or

$$H = \Sigma(\log_2(1 \ / \ p(i))$$

Equation 2

summed over all the symbols in the message.

Consider the frequency distribution of characters in a simple 100-character message:

Characters Found	A	E	H	R	G	F
Frequency	45	16	13	12	9	5
Entropy	1.15	2.64	2.94	3.06	3.47	4.32

Table 1

The total entropy is H = (1.15 * 45) + (2.64 * 16) + (2.94 * 13) + (3.06 * 12) + (3.47 * 9) + (4.32 * 5) = 221.76 bits. Shannon's equations predict that under ideal circumstances we should be able to represent the above message in 222 bits. We contrast these statements with traditional ASCII encoding, which uses 8 bits per character or 8 * 100 = 800 bits to represent the data in the target file. One can immediately see how much room for improvement via compression actually exists in a typical text file. Thus, Shannon's methods provide us with a lower bound with which to measure the effectiveness of any compression scheme.

D.   COMPRESSION STATISTICS

There are many ways to express the size reduction of a file after it has been compressed. In this paper we define the percentage of decrease (POD) via the formula

POD = (*change in file size / original file size*) * 100,

Equation 3

where the change in file size = original file size − compressed file size.

In the event that the compression fails (bloats the file) the resulting POD will be negative.

5

E. STATISTICAL VS. DICTIONARY MODELING

A compression model is a collection of data and rules used to map each input symbol to an output code. The term symbol is intentionally vague, as a symbol can represent an arbitrarily long string of bits deemed useful by the chosen model. A compression program uses its model to accurately define the probabilities for each input symbol. The model allows the program to produce an appropriate code for each symbol. Lossless compression is generally implemented using either statistical or dictionary modeling.

In statistical modeling the compression program analyzes the source file and finds the most common symbols. Typically, statistical modeling uses fixed-length symbols. Then each input symbol is assigned a replacement code. Replacement codes are normally short for the more common symbols and longer for the less common ones. An output file is then built by representing each symbol in the source file by its replacement code. When all the replacements are made the output file should be shorter than the source file since the more common symbols all get shorter representations. Even though some symbols get longer representations, they occur only infrequently in the text, thus they have a limited effect on the output file length.

In dictionary modeling a single code is used to replace a string of fixed-length symbols. Equivalently, one could say that symbols are of variable length. Regardless of the interpretation, a program using a dictionary model merely builds a list of the most frequent words, phrases, bit strings, or input symbols found in the source file. Each entry in the dictionary is then assigned a fixed-length replacement code, which can be thought of as simply an index into the dictionary.

6

The compression program uses its dictionary much like the authors of a thesis use the list of references at the end of the paper. Instead of writing out the full citation for a referenced paper, a number is used to indicate the citation's index within the bibliography. The reader of the thesis decompresses the citation by finding the indicated position within the list of references and mentally replaces the number with the full citation. Similarly, the dictionary compression program replaces input symbols with their assigned replacement codes (indices), and the decompression program does the inverse.

To draw a distinction between statistical and dictionary modeling, note that in statistical modeling fixed-length symbols are replaced by variable-length codes, but in dictionary modeling variable-length symbols are replaced by fixed-length codes.

F.   STATIC VS. ADAPTIVE MODELS

The models in the previous section were described in a 'static' way, i.e., each model was created only after the *entire* source file was completely analyzed. This means two passes through the source file are required – the first to build the model and the second to do the actual symbol replacement. If a program is compressed using a static model then the decompression program must also have access to the same model in order to transform the codes in the compressed file back into the symbols from the original source file. In many cases, this means that the model will have to be included as part of the compressed file. Model overhead information is normally located at the beginning of the compressed file in an area referred to as the file header. Header overhead is one of the major performance burdens of static methods.

An alternative to static modeling is *adaptive* modeling (sometimes also referred to as dynamic modeling). In adaptive modeling the compression program updates the

model *as the output file is being created.* This means that the output codes produced by the compression program might have different meaning depending upon their relative position in the output file.
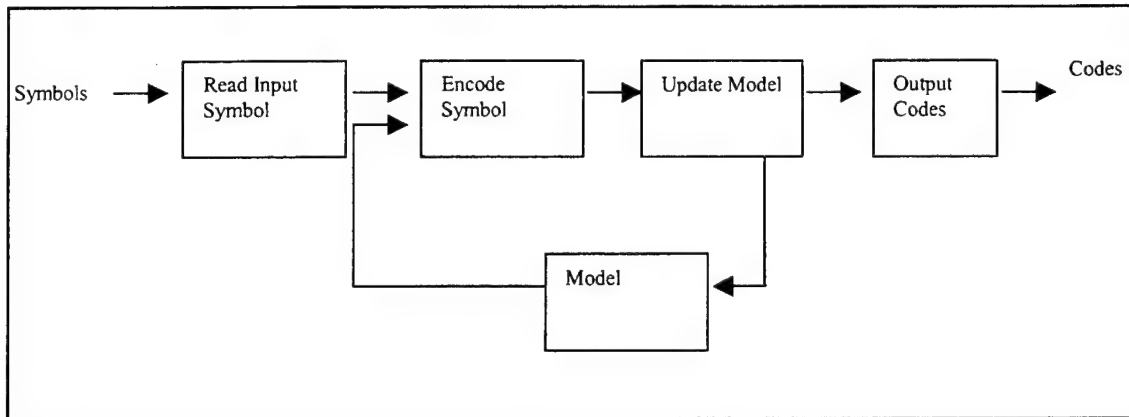

Figure 1: General Adaptive Compression [6]

There are several advantages to adaptive modeling. First, only one pass is required to encode the source file. Second, adaptive techniques quickly tune themselves to the file they are encoding and are thus better able to compress files containing markedly different types of data. Third, modeling information need not be explicitly included in the output file header as it is with static techniques. Instead, the adaptive decompression program simply begins with the same initial model as the compression program did, and then updates its model each time it reads a code from the compressed file. Thus, although the decompression program's model is in a constant state of change, it is always identical to the compression program's model at the same point in the process. Obviously, adaptive techniques rely on the compression and decompression

8

programs both beginning with the same model, and both updating the model in exactly the same fashion. The following diagram depicts the decompression process.
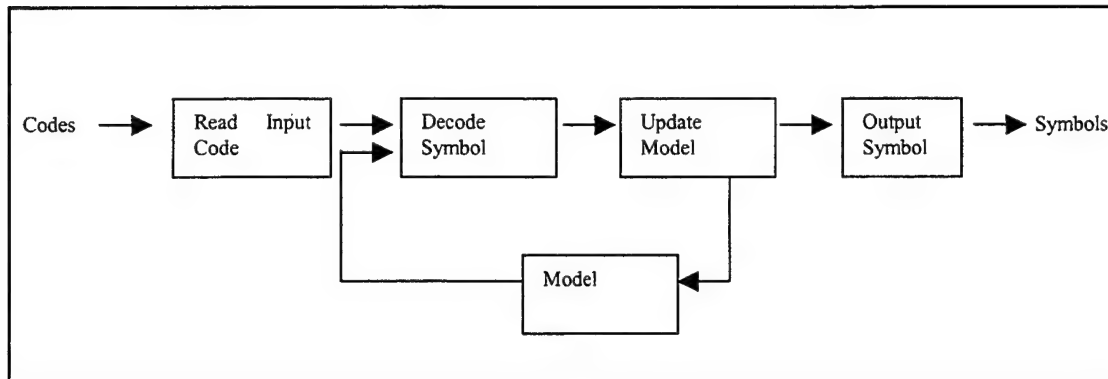

Figure 2: General Adaptive Decompression [6]

G.   SURVEY OF LOSSLESS COMPRESSION TECHNIQUES

There are literally hundreds of serious data compression programs available on the web. The interested reader is referred to the excellent compression resource, "The Data Compression Library" [7]. We do not survey these compression implementations. Instead, we present the foundational techniques from which the current generation of compression programs has sprung. In this way we hope to paint a clear picture of the field of compression, and to show where our methods fit into the field.

A word of warning for those who do decide to explore the world of compression via the Internet: The vast majority of commercial applications are enhancements and hybrids of the more basic techniques, which follow in this section. These applications are typically tuned for specific data or specific performance (speed, memory footprint, or file size). Few limit themselves to any one compression technique. Instead, multiple

9

techniques are used in an effort to squeeze the maximum possible compression out of source files. Naturally, this leads to increased algorithm and program complexity. In short, the Internet may not be the best place to learn the fundamentals of compression. Two excellent books on the subject are "The Data Compression Book" [6] and "Compression Algorithms for Real Programmers" [8].

Most of the following techniques can use either a static or adaptive (dynamic) model. Interestingly, most statistical approaches seem to have been originally conceived in a static manner and later explored using adaptive methods. On the other hand, dictionary techniques typically began as adaptive methods, and only later began to be investigated statically. The techniques that follow are presented using the method with which they were originally developed.

1. Run Length

Long runs of repeated characters are one of the simplest forms of redundancy found in a file [9, 10]. Consider the string of repeated characters,

AAAAAAAABBBCCCCCCCDDDDEEEEEEEEE.

A run length encoding scheme might represent the string as

8A3B7C4D9E.

Unfortunately, typical text does not exhibit these types of patterns. There are some applications of this technique - the runs of black and white pixels on a fax image for example, but in general it is not particularly suited as a stand-alone method. Typical text compression using run length encoding is less then 5%. Of course, greater compression results can be achieved with specific data (e.g., fax images).

2. Shannon-Fano

This technique uses a static statistical model to build a binary tree in a top-down fashion. Each leaf of the tree represents an input symbol, while the path from the root node to a leaf gives the leaf's replacement code. The replacement codes generated by the algorithm share the following properties:

- Codes are of variable length.

- High probability codes are shorter then low probability codes.

- No code is a prefix of any other code from the same tree.

The Shannon-Fano algorithm [11] proceeds through the following steps:

1. Build a frequency distribution for the input symbols.

2. Sort the list of symbols in descending order by frequency.

3. Initialize the replacement code for each symbol to be null.

4. Divide the list in two parts with the total frequency count of the upper half being as close as possible to the total frequency count of the lower half.

5. Append a 0 to the replacement code of each symbol in the upper half and a 1 to the replacement code of each symbol in the lower half.

6. Recursively apply steps 4 and 5 to each partial list until each list contains exactly one symbol.

Although an excellent technique, Shannon-Fano encoding has generally been replaced by Huffman encoding, which is marginally superior.

3. Huffman

Standard Huffman encoding [2] uses a static statistical model to build a binary tree in a bottom-up fashion. The codes generated by the tree share all the properties of

11

those of those generated by Shannon-Fano and have the added advantage of being provably optimal. Optimal in this case means that there isn't a better set of *integral-length* replacement codes than those generated by the algorithm.

The Huffman algorithm proceeds as follows:

1. Build a frequency distribution for the input symbols.

2. Create a collection of single-node trees C each associated with a symbol and its frequency.

3. Let t_1 and t_2 be two trees with the lowest frequency in Collection C. Replace t_1 and t_2 with a single tree t_3, formed by attaching t_1 and t_2 as the left and right descendants of the new node. The frequency associated with t_3 is the sum of the frequencies of t_1 and t_2.

4. While more than one tree remains in C, repeat step 3.

Though optimal, Huffman encoding does not quite reach Shannon's predicted entropy limit. Consider the breakdown of our imaginary 100-character message and its associated Huffman tree shown below:

Symbol	Frequency	Entropy (bits)	Total Entropy (bits)	Huffman Code Length (bits)	Total Huffman Code Length (bits)
A	45	1.15	51.75	1	45
E	16	2.64	42.24	3	48
H	13	2.94	38.22	3	39
R	12	3.06	36.72	3	36
G	9	3.47	31.23	4	36
F	5	4.32	21.60	4	20
	100		221.76		224

Table 2: Frequency Table for 100-Character Message
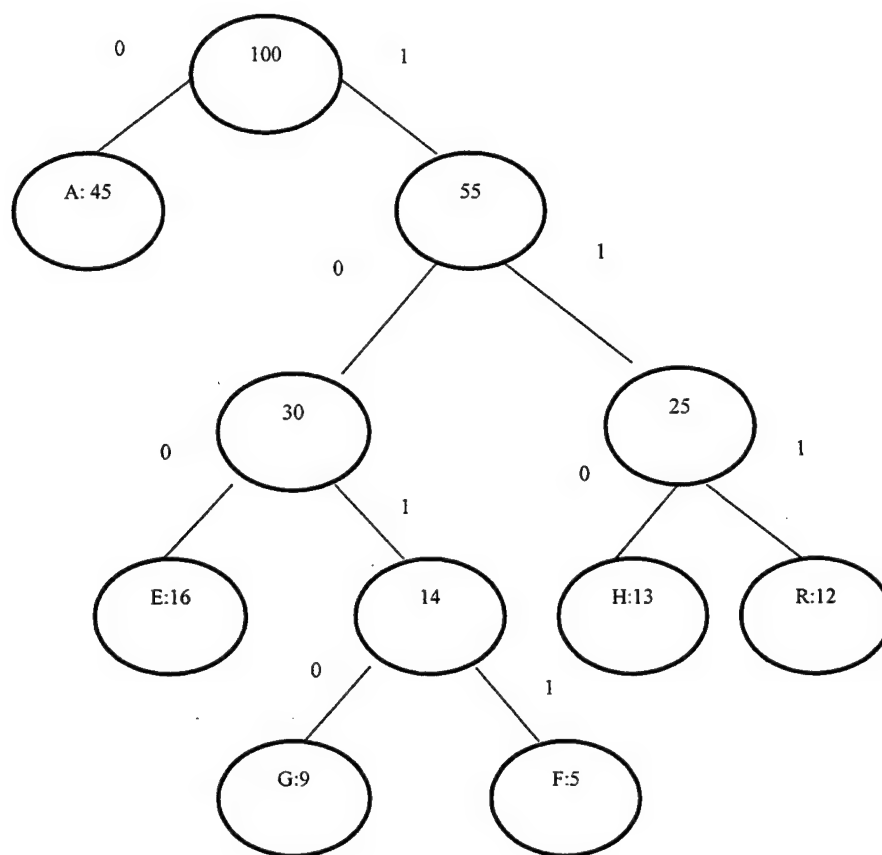

Figure 3: Huffman Tree

We see that while the total information content of the message is 221.76 bits, Huffman requires 224 bits to actually encode it. While this is not bad, it is not *truly* optimal. The deviation from the predicted value is due to the inability of the method to accurately represent the fractional entropy of each symbol. Thus, while there is no better integral length encoding scheme, there is still room to improve on Huffman's algorithm. Note that Shannon-Fano encoding will also require 224 bits for this file.

13

4.   Arithmetic

Arithmetic coding [12, 13, 14] can use either a static or an adaptive statistical model. It completely discards Huffman's idea of replacing an input symbol with a specific code, and instead replaces the entire string of the input symbols in a message with a single floating point number between 0 and 1. For this reason it does not suffer the discrete code-length limitations of Huffman encoding. Arithmetic encoding uses a probability distribution to assign a proportionate range between 0 and 1 to each input symbol. It is typically able to approach the Shannon theoretical minimum - sometimes yielding improvements of up to 10% over standard Huffman encoding. The major drawback of the technique is that it is computationally intensive and therefore slow.

Arithmetic Encoding Algorithm:

1. Build a probability table for all the input symbols.

2. Establish proportionate lower bounds (L_i) and upper bounds (U_i) between 0 and 1 for   each symbol based upon its probability of occurrence.

3. low = 0.0, high = 1.0, range = 1.0

4. Read in the next symbol to encode S_i.

5. range = high – low.

6. high = low + range * U_i.

7. low = low + range * L_i.

8. While more symbols remain to encode, repeat step 4.

9. Output the floating point number between low and high that has the shortest binary representation.

Consider a hypothetical message written in a 3-symbol alphabet D, A, X with the following probability distribution and bounds. Notice that each character is assigned the portion of the 0 to 1 range that corresponds to its probability of appearance.

Symbol Index (i)	Symbol (S_i)	Probability (P_i)	Lower Bound (L_i)	Upper Bound (U_i)
1	D	0.20	0	0.20
2	A	0.18	0.20	0.38
3	X	0.62	0.38	1

Table 3: Probability Table for Arithmetic Encoding

To see how the method works, we encode the message "DXXA" one symbol at a time. The first symbol "D" has a range from 0 to 0.20 so we know that the final encoded value for the message must fall within this range. Each time we add a new symbol we further restrict the range of our final value that represents the entire message. Thus, the next symbol "X" restricts us to the last 62% of the current range, or 0.124 to 0.2. The next symbol is another "X" so we again restrict the output to the last 62% of the current range, or 0.17112 to 0.2. The final symbol "A" limits us to between 20% and 38% of the current range, or 0.176896 to 0.1820944. Now we pick the value in the final range with the shortest binary representation. This is accomplished with some relatively straightforward binary arithmetic. In this case the shortest value turns out to be 0.1796875 = 0.0010111 base 2. The message is encoded as a unique floating-point value between 0 and 1. We require 7 bits to compress 4 symbols (about the same performance as Huffman on this particular example).

Consider the resulting partition of the number line shown below to see how any string in our alphabet could be similarly, yet uniquely, encoded. Notice that there is exactly one path to any given "leaf" of our fuzzy ternary tree.

15
**Table 4: Partitioning of the Number Line by Arithmetic Encoding:
A Fuzzy n-ary Tree (intervals not to scale)**

5. Ziv and Lempel

Jacob Ziv and Abraham Lempel are essentially the fathers of adaptive dictionary compression. Their first algorithm, commonly referred to as LZ77 [14], uses previously-seen text as a dictionary. The algorithm replaces variable-length phrases (symbols) from its input stream with fixed-length indices (codes) into its dictionary. What makes this an adaptive method is that its dictionary is literally a sliding window consisting (in a typical implementation) of the last 4k bytes of data from the input stream. Thus, while new groups of symbols are being read in to a *look-ahead buffer*, the algorithm is searching for matches between the look-ahead buffer and all strings located in the previous 4k bytes of data (the dictionary). If a match is found then an ordered triple (a, b, c) is sent to the output file. The triple consists of:

- An index a into the previous 4k of data.

- The length b of the match.

- The symbol c immediately following the match in the look-ahead buffer.

16

If no match is found then a and b are 0 and c is the first symbol in the look-ahead buffer. The text window and look-ahead buffer then slide forward sufficiently to shift the matching symbol(s) out of the look-ahead buffer and into the dictionary. The process then repeats.

The amount of compression achieved by this method depends upon the dictionary entries being sufficiently longer then the ordered triples they are replaced with. Here is a simplified example of the process:
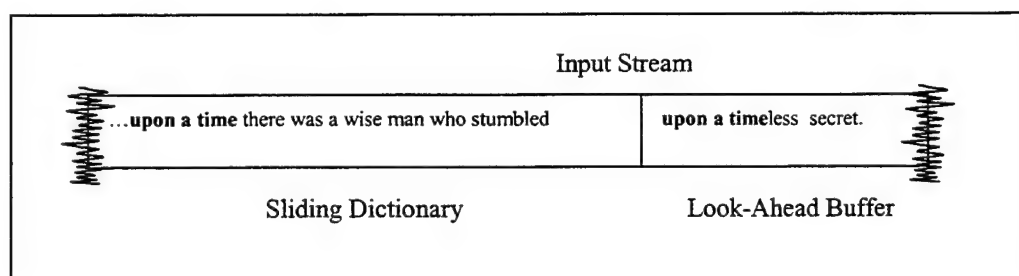

Figure 4: LZ77 Algorithm

Suppose our sliding dictionary is 64 bytes long and the look-ahead buffer is 16 bytes long. Further suppose that the first occurrence of the word "upon" begins at position 35 in the current sliding dictionary. Since a match has been found, our compression program will now send the ordered triple "35", "11", "l" to the output file. Since the dictionary is 64 bytes long 6 bits are required to represent each of the index and length of the match, plus 8 bits for the ASCII character "l". Thus, we have just encoded an 11 * 8 = 88 bit phrase in 6 + 6 + 8 = 20 bits.

There are two problems with LZ77. First, since the dictionary is constantly sliding, the algorithm sometimes actually throws away valuable old strings for worthless

17

new ones. This is a potential drawback to adaptive methods in general. Second, the length of pattern matches is limited to the length of the look-ahead buffer. Increasing the size of the look-ahead buffer, however, has a nasty side effect – it proportionately increases the number of string comparisons that must be performed against the dictionary. This creates a significant performance problem. Thus, LZ77 is not able to store long strings to its dictionary even when it would be highly profitable to do so.

A second adaptive dictionary technique developed by Ziv and Lempel, referred to as LZ78 [16], uses a different approach to building its dictionary. Instead of maintaining a sliding window into the preceding text, LZ78 incrementally builds its dictionary from strings found in *all of the preceding text*. The algorithm does this by *growing* dictionary entries one character at a time. For example, the first time the string "hello" is encountered it is not put in the dictionary. Instead, "h" is added to the dictionary. The second time "hello" is encountered it is still not put in the dictionary. Instead, "he" is added. The third occurrence puts "hel" into the dictionary, and so on until the fifth occurrence of the string "hello" actually causes "hello" to become part of the dictionary. This incremental procedure of slowly adding a string to the dictionary does a good job of eventually getting all of the frequently used strings into the dictionary. Once the dictionary begins to accurately model the source file, large savings can be achieved as the algorithm replaces long frequently occurring strings with short fixed-length indices.

LZ78 does not suffer from the same limitations as LZ77. It is able to handle long strings and once it adds a string to its dictionary it remains there until the entire file is processed. LZ78 has its own difficulties, however. In LZ77 the dictionary is easier to manage. It is a fixed block of already processed data. In LZ78 the dictionary starts with

18

nothing but the null string and grows. It must be managed with a data structure, (typically an n-ary tree that looks remarkably like the fuzzy tree shown earlier for arithmetic encoding) and limited to some finite size (typically around 2^{16} entries). Despite these problems LZ78, like LZ77, was a groundbreaking compression approach. Terry Welch later enhanced LZ78 – the resulting algorithm is commonly referred to as LZW.

III. MATHEMATICAL FOUNDATIONS

A. INTRODUCTION

In this chapter we will discuss the necklace algorithm and the properties of the necklace algorithm that we find to be useful for compression. First we explore properties of binary n-tuple necklaces. Next, we consider equivalence classes of necklaces and how to enumerate the equivalence classes for a given n using the Burnside formula [17]. Then we use the Theta Algorithm [3] to generate all of the equivalent necklaces for a given n. Next, we consider the space reduction that can be realized from the sub-cyclic properties of necklaces. Finally, we describe a close relative to the necklace classes, the Lyndon Words.

B. NECKLACE CLASSES

The binary n-tuples are strings of 0's and 1's of a fixed length n. The circular rotation of a binary n-tuple produces a cyclic equivalence class of binary n-tuples called a necklace class. We represent each necklace class by the numerically largest n-tuple in the class. This gives us $Z[n]$ necklaces representing the 2^n strings from 000...0 to 111...1, where $Z[n]$ is defined in equation 4. The necklace algorithm provides an efficient way to list these necklace classes. The necklace algorithm typically produces the necklaces in the order from largest to smallest. There is no difference in which way we represent these strings and an equivalent version of the necklace algorithm could invert the order of the necklace classes.

1. Equivalence Classes and the Burnside Formula

A necklace is an equivalence class of strings of bits of length n that can be rotated to obtain equivalent aspects of the same necklace. Thus, two necklaces are said to be inequivalent if no matter how rotated, one cannot be transformed into the other. Z[n] gives the number of inequivalent necklaces of length n, where Z[n] is determined by using an instance of the Burnside enumeration formula:

$$Z[n] = (1/n)\Sigma(\phi(d)*2^{(n/d)}), \text{ for } d = 1 \text{ to } n \text{ and } d \text{ is a divisor of } n.$$

Equation 4

Here $\phi(d)$ is Euler's Totient Function, defined as the number of positive integers less than d and relatively prime to d.

The formula in equation 4 enumerates the necklace classes for a given n, and the necklace algorithm tells us what the necklaces are. To illustrate the use of the formula we consider an example:

Let n = 6, then

$$Z[n] = 1/6(1*2^6 + 1*2^3 + 2*2^2 + 2*2) = 1/6 (64+8+8+4) = 84/6 = 14.$$

$$d = 1 \qquad d=2 \qquad d=3 \qquad d=6$$

When d = 1, only 1 is relatively prime to 1. When d = 2, again only 1 is relatively prime to 2. When d = 3, 1 and 2 are relatively prime to 3. When d = 6, both 1 and 5 are relatively prime to 6.

We identify two upper bounds for the number of necklace classes of length n. A simple upper bound is $(2^{(n+1)})/n$. A tighter upper bound is $2^{((n+1)-\lceil \log_2 n \rceil)}$. When n = 6, we

know that there are 14 necklace classes. If we compute the first upper bound we get 21.33 while the second upper bound yields 16. We use the tighter upper bound in the implementation of our compression algorithms.

2.   Necklace Algorithm

The necklace algorithm is fairly straightforward. First we need to define the θ step. This operation $\theta: V^n \to V^n$ is defined as follows: $\theta(a_1, a_2, \ldots, a_n) = (b_1, b_2, \ldots, b_n)$ where $b_i = a_i$ for $i = 1, 2, \ldots, j\text{-}1$ and j is defined as the largest subscript such that $a_j > 0$ and $a_k = 0$ for all $k > j$. Then

$$b_j = a_{j-1}, \quad b_{j+t} = b_t \text{ for } t = 1, 2, \ldots, n - j.$$

Necklace Algorithm (for necklaces of length n) [3]

0. The initial necklace is $11\ldots1 = 1^n$;

1. To find the $i+1^{st}$ necklace apply θ to the ith necklace;

2. The resulting string is the next necklace if and only if $j|n$.

3. If j does not divide n, then apply $\theta^2, \theta^3, \ldots, \theta^k$ to the ith necklace until the smallest k is found so that $j|n$. The resulting string is the next necklace.

4. If the necklace found is not the last necklace, namely, 0^n, return to step 1.

Note: If step 2 is modified such that $j = n$, we produce a list of all Lyndon words of length n (Lyndon words are discussed in more detail in paragraph B).

To illustrate and to clarify the algorithm, start with the largest n-long necklace (an n-long string of 1's), subtract one from the last 1 in the string and copy the string $a_1 \ldots a_{j\text{-}1}$ until an n-long string is formed. Now do the "j divides n check". If $j|n$ then the string

23

formed is a necklace, if not, subtract one again from the last non-zero in the current string and copy to form an n-long string.

As an example consider the necklaces produced when $n = 6$:

111111		This is the first necklace $(a_1, a_2, \ldots, a_6)$.
111110	$j = 6$	Since 6 divides 6, this is a necklace.
111101	$j = 5$	Since 5 does not divide 6, this is not a necklace.
111100	$j = 6$	Since 6 divides 6, this is a necklace.
111011	$j = 4$	Since 4 does not divide 6, this is not a necklace.
111010	$j = 6$	Since 6 divides 6, this is a necklace.
111001	$j = 5$	Since 5 does not divide 6, this is not a necklace.
111000	$j = 6$	Since 6 divides 6, this is a necklace.
110110	$j = 3$	Since 3 divides 6, this is a necklace.
110101	$j = 5$	Since 5 does not divide 6, this is not a necklace.
110100	$j = 6$	Since 6 divides 6, this is a necklace.
110011	$j = 4$	Since 4 does not divide 6, this is not a necklace.
110010	$j = 6$	Since 6 divides 6, this is a necklace.
110001	$j = 5$	Since 5 does not divide 6, this is not a necklace.
110000	$j = 6$	Since 6 divides 6, this is a necklace.
101010	$j = 2$	Since 2 divides 6, this is a necklace.
101001	$j = 5$	Since 5 does not divide 6, this is not a necklace.
101000	$j = 6$	Since 6 divides 6, this is a necklace.
100100	$j = 3$	Since 3 divides 6, this is a necklace.
100010	$j = 4$	Since 4 does not divide 6, this is not a necklace.
100001	$j = 5$	Since 5 does not divide 6, this is not a necklace.
100000	$j = 6$	Since 6 divides 6, this is a necklace.
000000	$j = 1$	Since 1 divides 6, this is a necklace.

There are fourteen necklaces generated by the Necklace Algorithm; that is the number given by the equation 4. Additionally, it is easy to see that a string that ends with a 1 (except all 1's, of course) can never be a necklace, since that 1 could be rotated to the

24

front of the n-tuple and the rotated n-tuple, being larger, will have already appeared on a previous necklace in the lexicographic listing of the necklaces. For each value of j, the string $a_1, a_2, \ldots, a_{j-1}$ is a Lyndon word of length j. (See paragraph C for a discussion of Lyndon words.)

3. Necklace Algorithm Pseudo Code

```
DESCRIPTION: Finds all the necklace classes of length n. Note the indexing
scheme used by the bit arrays of this method. The most significant bit is
considered to be at index 1 while the least significant bit is at index n.

PRECONDITION: The array classes are large enough to hold all the necklace
classes generated by the algorithm.

POSTCONDITION: classes contains all the necklace classes of length n sorted in
descending numerical order.

void getNecklaceClasses(/* IN    */ int n,
                        /* OUT */  BitArray[] classes)
{
    BitArray c = 2^n - 1;       // the first class is all 1's
    classes[0] = c;             // store it at index 0 of classes
    int k = 1;                  // index to store next class at
    while (c > 0)
    {
        int j = c.leastSig1();  // j gets index of least sig 1 in c
        c[j++] = 0              // replace least sig 1 in c with 0
        int i = 1;
        while (j <= n)          // copy over, copy over, ...
          c[j++] = c[i++];
        if (j | n)              // j-check, if TRUE it's a class
          classes[k++] = c;
    }
}
```

Figure 5: The Necklace Algorithm Pseudo Code

4.   Sub-cyclic Properties

As mentioned previously, the necklace algorithm generates all of the necklace classes for a given n. These necklaces are listed lexicographically from the largest (1^n) to the smallest (0^n). This is contrary to normal order, but the results are equivalent to an ordering from smallest to largest and it is easy to translate between the necklaces listed from smallest to largest.

One of the most interesting properties of the necklace algorithm is that the sub-cyclic rotations also occur for each divisor of a given n. That is, all the m-long necklaces appear where m is a factor of n. The factors of n tell us the length of the sub-cyclic or repeating strings for the given n. Using the Mobius function [17], in place of the totient function, one may enumerate the sub-cyclic rotations for the given factors of n. In fact, regardless of the value of n, the number of sub-cyclic rotations of length m will always be the same for the factors m of n. In other words, since 1 is a factor of every n, there are two sub-cyclic rotations of length 1, namely 0 and 1 and the necklace (10) appears in every necklace class when n is even. Thus, when m|n, each m-long necklace will appear in the necklace algorithm for the parameter n.

In the example given where n = 6 and has the factors 1, 2, 3 and 6, the necklaces that appear are all the necklaces for m = 1, 2, 3 and 6. If we modify the enumeration formula in equation 4 by substituting for $\theta(d)$ the function $\mu(d)$, where $\mu(d)$ (the Mobius function) is defined by

$\mu(1) = 1;$

$\mu(n) = (-1)^k$ when n has k distinct prime factors;

$\mu(n) = 0$ when n has a square or higher order factor, we obtain the expression on the right hand side of equation 5.

We obtain the number of necklaces of length n by applying this modified enumeration formula on each of these factors m of n.

$$N(m) = (1/m)\Sigma(\mu(d)*2^{(m/d)}).$$

Equation 5

So, when n is 1, there are 2 necklaces; when n is 2, there is 1 necklace. We determine the number of necklaces when n is 3 to be $1/3(1*2^3 -1*2) = 1/3(8-2) = 6/3 = 2.$ These are the necklaces (110 and 100). Finally, we determine the number of necklaces when n is 6 as $1/6(1*2^6 -1*2^3-1*2^2+1*2) = 1/6(64-8-4+2) = 54/6 = 9.$ Therefore, 9 of the 14 necklace classes will be of length 6 as can be determined from our listing above of the necklace algorithm. Thus the total number of necklaces, including all sub-cyclic necklaces, for n = 6 is (2+1+2+9) = 14.

These sub-cyclic rotations are important in our version of the data compression algorithms, because, it is cheaper to represent a string with fewer rotations, than one with greater rotations. Namely, it costs only 1 bit to represent a necklace with sub-cyclic length 2, where it costs 3 bits to represent all of the possible rotations of a necklace of length 6.

C.   LYNDON WORDS [18]

Although the two lossless compression techniques discussed in this paper do not use Lyndon words, we cover them because of their relation to necklaces and because we recommend them for future research.

A *k*-ary *necklace* is an equivalence class of *k*-ary strings under rotation. We take the lexicographically smallest such string as the representative of each equivalence class and use this in the output of the program. A *Lyndon word* is an aperiodic necklace representative.

The illustration below shows the 6 binary necklaces with 4 beads and the corresponding equivalence classes of strings. The three Lyndon words are 0001, 0011, and 0111.

0 0 0 0	0 0 0 1	0 0 1 1	0 1 0 1	0 1 1 1	1 1 1 1
	0 0 1 0	0 1 1 0	1 0 1 0	1 0 1 1	
	0 1 0 0	1 1 0 0		1 1 0 1	
	1 0 0 0	1 0 0 1		1 1 1 0	
Figure 6: Lyndon words of length four.

Equation 6 gives the explicit formula for the number of Lyndon words of length n over a *k*-ary alphabet.

$$N_k(n) = (1/n)\Sigma(\mu(d/n)*k^d)$$

Equation 6

IV.   ROTATIONAL TREE APPROACH

A.   INTRODUCTION

In this chapter we exhibit the bulk of our research efforts. Our efforts to find a compression application involving the binary necklace classes discussed in section III, led us to The Rotational Tree Approach (RTA). Our motivation for exploring the approach arises from the following observation. Let A be the set of all bit strings of length n. Further, define B to be the set of all necklace classes of length n. Consider the onto mapping from the domain A to the codomain B, where each n-tuple maps to its representative necklace class in B:

Bit Strings of Length n
Necklace Classes

Figure 7: Mapping of Bit Strings to Their Necklace Class

This mapping is attractive from a compression standpoint because there is a significant space reduction between the number of bit strings and the number of necklace

classes to which they map since there are 2^n bit strings of length n and less than $2^{(n+1)}$ / n

necklace classes.

n	Bit Strings	Classes	Decrease
6	$2^6 = 64$	14	78%
12	$2^{12} = 4,096$	352	91%
16	$2^{16} = 65,536$	4,116	94%
20	$2^{20} = 1,048,576$	52,488	95%
24	$2^{24} = 16,777,216$	699,252	96%
28	$2^{28} = 268,435,456$	9,587,580	96%
32	$2^{32} = 4.294,967,296$	134,219,796	97%

Table 5: Space Reduction Afforded by Mapping Strings to Necklace Classes

B. EXPLANATION

In order to take advantage of the resulting space reduction, our idea is to map each source symbol in A to its corresponding necklace class in B, and then represent that class with an index. We define the index i of an n-bit class as the position of the class in the ordered list of all n-bit classes as given by the Necklace Algorithm. Thus, by mapping a symbol to an index class we can effectively decrease the number of distinct symbols as well as the size of each such symbol. This sounds promising.

The difficulty is that there are many n-bit strings that map to the same index class. Thus, in order to reverse the mapping, which is necessary for decompression, additional information is needed; specifically, we need to know the number of rotations r originally used to transform the bit string to its necklace class.

30

What we have at this point is a vague model involving the quantities r (rotation) and i (index). What we need is a clever way to use them. As r and i are fixed in length (with respect to a given n) static Huffman encoding seems a good choice.

Our initial efforts revolved around a two-Huffman-tree approach. We proceed as follows: We first read n-bit symbols from a source file. We then break each symbol into an index i and a rotation r. We build one Huffman tree using all the r's and another using all the i's. Finally, we write the Huffman codes for each r, i pair to the output file, in the order in which they were first discovered.

Surprisingly (for us at least) this approach is a complete failure. It typically achieves very low levels of compression (often even bloating the source file). After some analysis involving comparisons against a standard single Huffman tree built with n-bit symbols, we draw the following conclusions concerning this failed two-tree approach:

- The i-Huffman tree is much narrower and shallower than a standard Huffman tree built with n-bit symbols. This means the codes produced by the i-Huffman tree are shorter. This is exactly the type of decrease in symbol number and size that we are looking for.

- The amount of statistical data (output file header) required for the two-tree approach is significantly less than that required for standard Huffman (more on this later).

- The added expense of the r-codes paired with every i-code completely erases the gains cited above.

Essentially, the r-codes are an added expense that the model cannot afford. What we need is a way to make the r-codes either smaller or else somehow more useful to the model. Our solution consisted of developing an approach involving multiple Huffman trees. It proceeds as follows: We first read n-bit symbols from a source file. Then we break each symbol into a rotation r and an i. We put the r's into one Huffman tree, and distribute the i's to a forest of Huffman trees based upon their associated r's. Finally, we write the Huffman codes for each r, i pair to the output file, in the same order in which they were discovered.

This approach puts the r-codes to work by using them to distribute the i-codes to not one, but many Huffman trees. This is advantageous, as each tree in the forest will be both narrower and shallower than the original i-tree, and as such will produce shorter codes. The next section refines this procedure.

C.   ALGORITHM

1. Build a static statistical model of the data as follows:

    a. Construct $n + 1$ empty frequency tables (indexed from 0 to n) where n represents the length in bits of the symbols read from the input stream.

    b. Read the next n-bit symbol S from the input stream.

    c. Determine the number r of rotations required to transform S into its necklace class representative c.

    d. Determine the index i of c in an ordered list of all n-bit necklace classes.

    e. If i does not exist in frequency table r, put i into frequency table r with a frequency count of 1. Else, increment the frequency count of i in frequency table r.

32

f. If r does not exist in frequency table n, put r into frequency table n with a frequency count of 1. Else, increment the frequency count of r in frequency table n.

g. While there are more symbols in the input stream, repeat step *a*.

2. Create a Huffman tree from each of the n + 1 frequency tables. The leaves of Huffman tree n represent rotations. The leaves of all other Huffman trees represent class indices.

3. Reset the input pointer to the beginning of the input stream.

4. Read the next n-bit symbol S from the input stream.

5. Determine r and i for S.

6. Write the Huffman code for r in Huffman tree n to the output stream.

7. Write the Huffman code for i in Huffman tree r to the output stream.

8. While there are more symbols in the input stream, repeat step 4.

D. EXAMPLE

Consider a hypothetical 54-character message and its resultant breakdown:

Message: acgCs7bnacgCs7bnacgCs7bnggCCCCssss77777bnbnbnbnbnbnbnn

Symbol	Binary Representation	Necklace Class	r	i	Frequency
a	01100001	11000010	1	26	3
c	01100011	11011000	6	18	3
g	01100111	11101100	5	10	5
C	01000011	11010000	6	21	7
s	01110011	11100110	1	13	7
7	00110111	11100110	5	13	8
b	01100010	11000100	1	25	10
n	01101110	11100110	4	13	11
					54

Table 6: Example Message Breakdown by RTA (n = 8)

33

Step 1 of the RTA algorithm constructs the following frequency tables:

i	Frequency
26	3
13	7
25	10

Freq Table 1

i	Frequency
8	3
21	7

Freq Table 6

i	Frequency
13	11

Freq Table 4

r	Frequency
4	1
5	2
6	2
1	3

Freq Table n = 8

i	Frequency
10	5
13	8

Freq Table 5

Figure 8: RTA Step 1: Build Frequency Tables

Step 2 of the RTA algorithm constructs a Huffman tree for each frequency table.
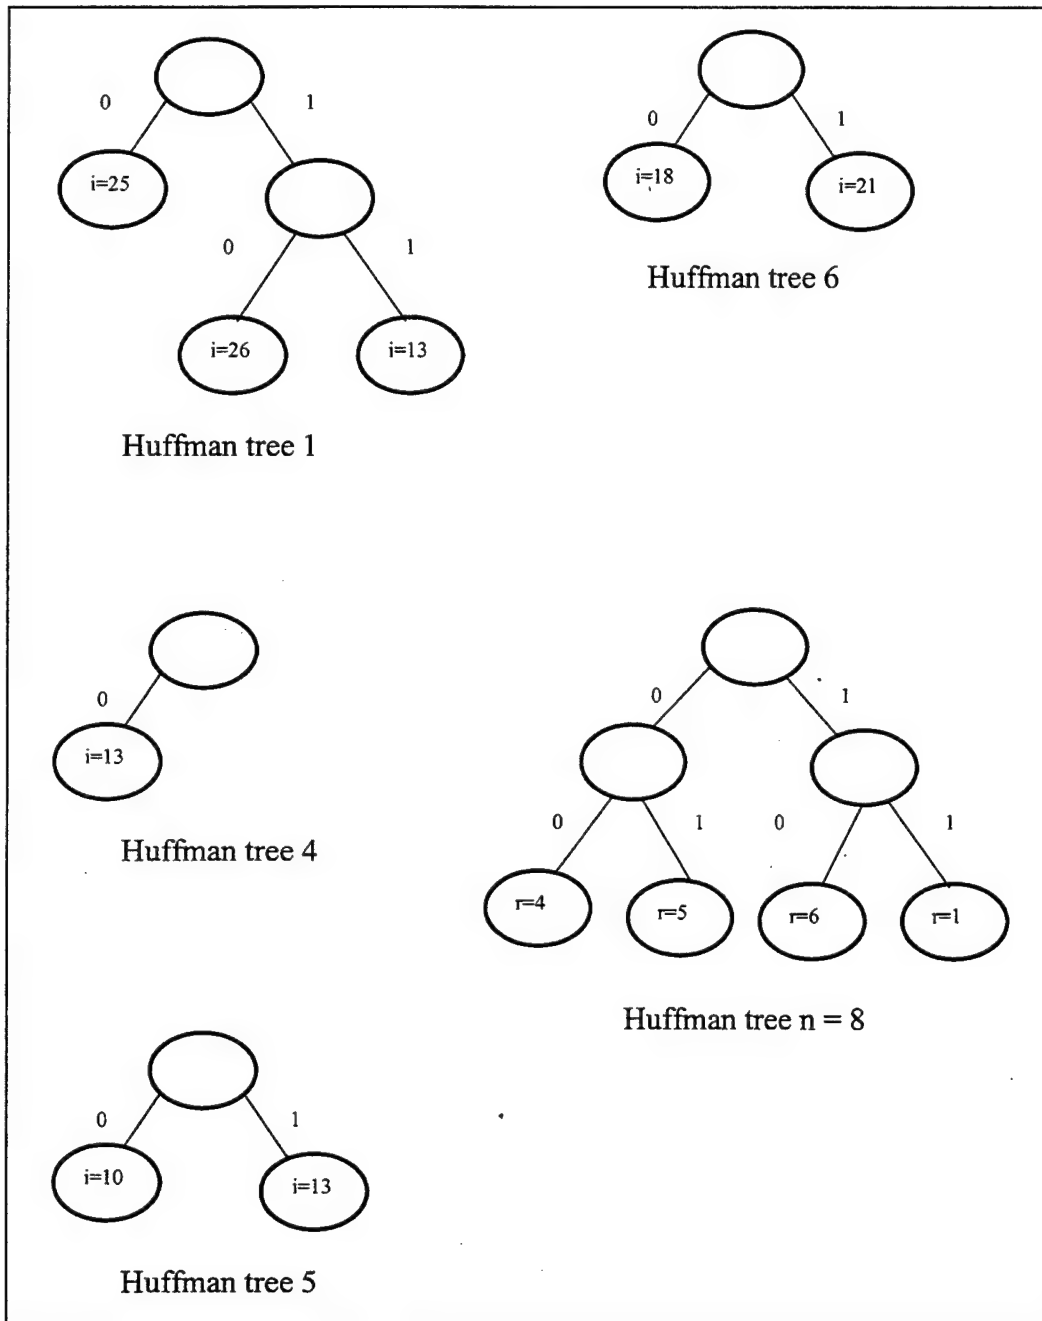

Figure 9: RTA Step 2: Build Huffman Trees

With the Huffman trees constructed, steps 3 thru 8 of the RTA algorithm begin the process of creating the output codes. This is accomplished by generating the r, i pairs to replace each input symbol in the message. Thus, the stream of input symbols

acgCs7bna...

is transformed into the stream of r, i pairs:

1, 26   6, 18   5, 10   6, 21   1, 13   5, 13   1, 25   4, 13   1, 26...

which then becomes the output stream:

11, 10   10, 0   01, 0   10, 1   11, 11   01, 1   11, 0   00, 0   11, 10...

by replacing each r with its Huffman code from tree n = 8 and each i with its Huffman code from tree r. For example, the r, i pair that corresponds to symbol "a", (found on table 6 above) is 1, 26. The code that represents r from the n=8 tree (figure 9 above) is 11. The code that represents the i component from Huffman tree 1 (figure 8 above) is 10. Therefore the input symbol "a" becomes the output 1110. Now move to the next symbol in the stream and repeat the process.

F.   INTERPRETATION OF RESULTS

We successfully implemented RTA in the Java programming language (see Appendix A) and collected empirical data (see Appendix B). The overall compression performance of RTA is roughly equivalent to that of standard Huffman encoding on both text and uncompressed bitmapped image data. Computationally, RTA is more expensive then Huffman encoding, but not prohibitively so. However, our implementation of RTA is space-hungry – requiring up to $5*2^n + (4*2^{(n+1)}) / n$ bytes just to build the tables needed to efficiently calculate r and i for all the input symbols. This calculation does not

36

include the memory needed to build the actual Huffman trees, which is data dependent but can also be very significant. The compression results for RTA are in fact cut off at n = 24 due to memory constraints - a typical 0.5 MB file requiring 86 MB of table building memory alone!

The compression performance of RTA is most easily explained by once again considering the failed two-tree approach discussed in part B above. By comparison with standard Huffman encoding, the two-tree approach has a favorable header size, and a favorable i-tree width and depth. Its fatal flaw is the overhead of the r-codes paired with every i-code. RTA is strapped by the same r-code overhead, but unlike the two-tree method, RTA uses its r-codes advantageously. By building a forest of i-trees instead of a single i-tree, RTA is able to generate much shorter i-codes. This allows the RTA forest to *approach* the performance of a single optimal Huffman tree - even with the added overhead of the r-codes. A useful way to view the Huffman forest created by RTA is as a *single distributed pseudo-Huffman tree* with the r-tree as the root, and the i-trees as leaves.
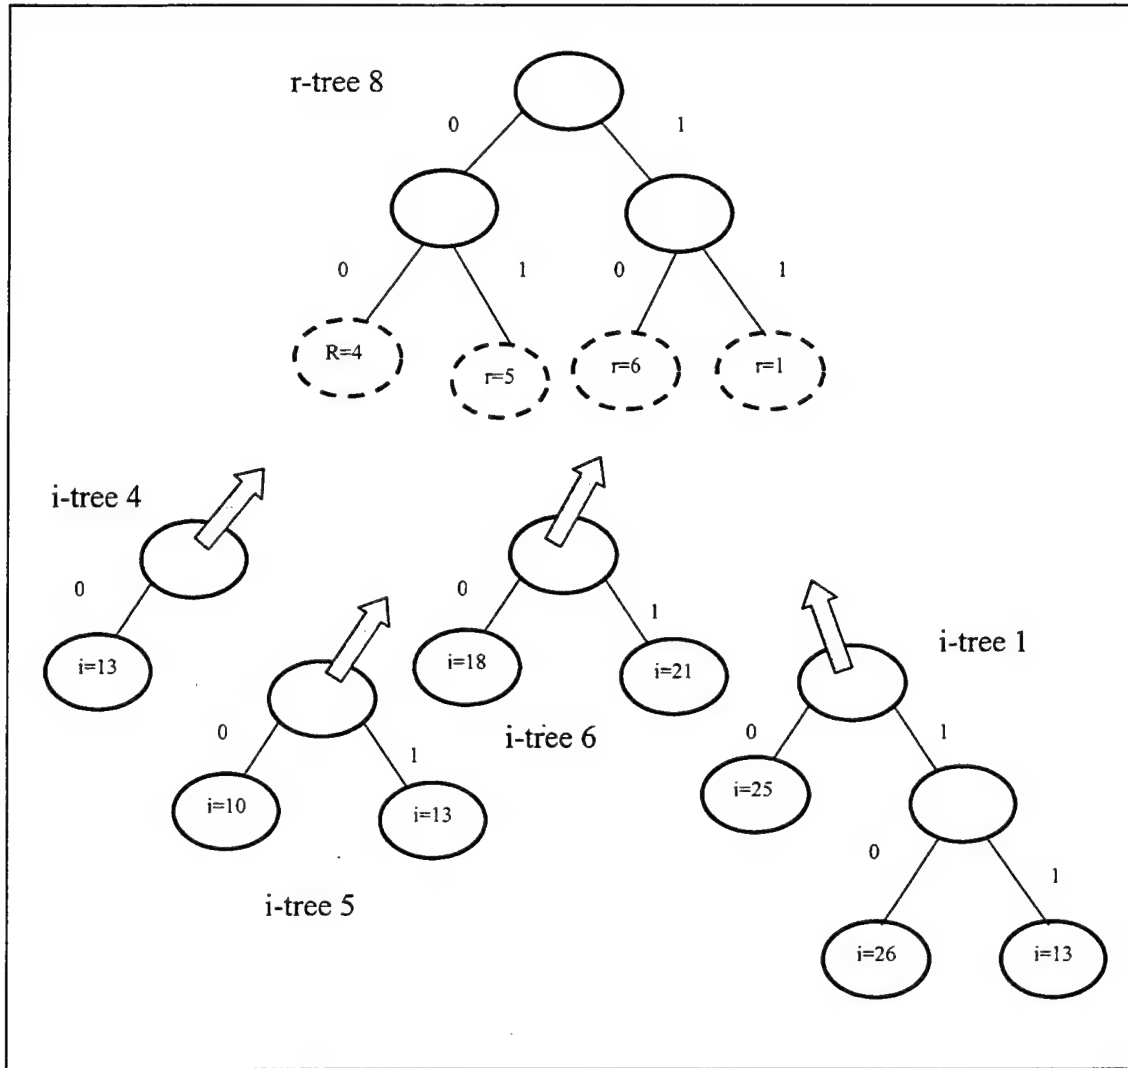

Figure 10: Distributed Pseudo-Huffman Tree Created by RTA

It is easy to see that this particular distributed tree is not a true Huffman tree and is therefore not optimal. Note that node i=10 from i-tree 5 is higher in the distributed tree than node i=13 from i-tree 1, even though node i=13 has a greater frequency.

After studying the tree breakdowns of our empirical data (see Appendix D for an example) we conclude that the weight of the distributed tree created by RTA is typically within 5% of the weight of an optimal Huffman tree. While it is theoretically possible for

the distributed tree to be a true Huffman tree, it would be an extremely rare occurrence when compressing real data.

Using this insight into the distributed tree of RTA, we conclude that the sum of the lengths of the i-codes and r-codes produced by RTA will approach the sum of the codes produced by a standard Huffman tree built from the same data. The problem is, if RTA can only approach Huffman encoding, then how is it that the empirical data shows RTA marginally outperforming Huffman encoding on almost half of the files in the test suite? The answer lies in the compression header. RTA requires less overhead than standard Huffman encoding to pass the statistical model from the compression program to the decompression program.

Model overhead is one of the drawbacks of static methods like Huffman encoding, the two-tree approach, and RTA. However, without a statistical model the decompression program has no way of uncompressing the codes in the compressed files back into the symbols of the source file, so inclusion of the compression model is necessary. Our implementation of Huffman, two-tree, and RTA all pass their static models to the decompression program in the same way. Each includes a frequency ordered list of all the leaves of their Huffman tree(s) in their respective header. The header includes other information as well (see Appendix E for details), but none so voluminous as the leaf list.

The symbols we shall encode in our Huffman code are binary n-tuples. A first pass through the data determines their probability of occurrence in the text. Armed with these probabilities a Huffman code can be made for the file under consideration and the leaves in the Huffman tree generated are the n-tuples appearing in the file. Then, in the

39

worst case, the leaf list for Huffman encoding will contain 2^n entries of n bits each. This means the leaf list for a standard Huffman tree can require up to n * (2^n) / 8 bytes of space.

In order to gain insight into the amount of space consumed by the leaf lists of RTA, we again turn to our failed two-tree approach. We noted earlier that two-tree had a significantly smaller header than standard Huffman encoding. This is a consequence of the space reduction afforded by using necklace class indices as leaves of the i-tree. Even though two-tree must put two leaf lists in its header, one for the r-tree and another for the i-tree, we see that the two-tree method still requires much less overhead than standard Huffman. The length and number of the leaves in the leaf lists of the two-tree method are governed by the properties of binary necklace classes discussed in chapter 3. The relevant information is summarized in the table 17.

	Leaf Length (bits)	Upper Bound on Number of Leaves
r-tree	$\lceil \log_2 n \rceil$	n
i-tree	$n + 1 - \lceil \log_2 n \rceil$	$2^{(n + 1 - \lceil \log_2 n \rceil)}$

Table 7: Leaf List Properties

An upper bound U on the maximum leaf list size (in bytes) for the two-tree approach is found by summing the product of the leaf length and the number of leaves for each leaf list then dividing by 8, or

$$U = (\lceil \log_2 n \rceil * n + (n + 1 - \lceil \log_2 n \rceil) * 2^{(n + 1 - \lceil \log_2 n \rceil)}) / 8.$$

The following table points out the drastic differences *possible* between the leaf lists of standard Huffman and those of the two-tree approach.

n	4	8	12	16	20	24
Standard Huffman	8	256	4,096	65,536	1,048,576	16,777,216
Two-Tree Approach	4	51	582	13,320	131,085	2,621,455

Table 8: Worst Case Leaf List Comparisons

When run on typical data, the actual differences between the leaf lists of the two approaches is never as dramatic as the worst-case scenario shown above. If it had been, two-tree would likely have been a viable approach.

We now draw comparative conclusions between the leaf lists of RTA and those of two-tree. The r-trees created by the two approaches are identical. Therefore, the r-tree leaf lists are identical. The difference between the two approaches is simply the number of i-trees created. Two-tree creates one long i-tree leaf list. RTA creates multiple shorter i-tree leaf lists. Since both approaches process the same r, i pairs, it is tempting to conclude that the concatenation of the smaller leaf lists of RTA would result in the longer leaf list of two-trees. If this were true, the overhead of the two approaches would be almost identical. An examination of the distributed tree depicted in table 16 above, however, reveals the flaw in this supposition. There are overlaps between the leaves of several of the i-trees. Specifically, i-trees 1, 4, 5 all have an i = 13 leaf. This demonstrates that in RTA some of the leaves may occur more than once in the header.

41

Thus, the header of RTA will be larger than that of two-tree by the number of overlapping leaves.

The actual number of overlapping leaves in RTA is data dependent. If the number of overlapping leaves is low, we expect a header size similar to that of two-trees and well below that of Huffman. If the number of overlapping leaves in RTA is high, it is possible that the header could approach or even exceed that of standard Huffman. The actual header sizes found for the test suite files using RTA and standard Huffman encoding are shown below.

Table 10: Header Size for Standard Huffman Encoding

Tables 9 and 10 demonstrate that the RTA header is in fact typically smaller than the header of standard Huffman encoding at n = 8. Further, it is apparent that as n increases the gap in the header size difference increases in favor of RTA over Huffman. This fits well with the empirical data (see Appendix B) that shows RTA performing best at large values of n's. Thus, we have probably identified the key element responsible for the (limited) success of RTA – decreased header size. This is no surprise as headers are the likely place to economize over the provably optimal encoding

G.   SUMMARY

We now summarize our conclusions from the previous section regarding RTA vs. standard Huffman encoding.

1. RTA compresses typical text data to within ±0.5% of Huffman encoding.

2. RTA is computationally more expensive than Huffman encoding, though not prohibitively so.

43

3. RTA is space (memory) inefficient to the point of being infeasible.

4. The non-header portion of a file compressed by RTA typically comes within 5% of the non-header portion of the same file compressed by standard Huffman encoding.

5. RTA has a more compact header than standard Huffman encoding. The difference between the headers increases as n increases. Thus, RTA performs best on large files with a high n.

V. INDEXED TREE APPROACH

A.   INTRODUCTION

In this chapter, we attempt to improve upon RTA by causing the distributed tree to more closely approach an optimal Huffman tree. We also seek to further decrease the size of the header and to reduce the memory requirements of our earlier approach.

One way to improve the distributed tree created by RTA is to decrease the depth and breadth of the i-trees. It is tempting to conclude that this can be accomplished simply by increasing the total number of i-trees. Unfortunately, increasing the number of i-trees requires an increase in the length of each r-code, which could prove detrimental to the overall compression ratio. Thus, we consider a more conservative approach to improving the distributed tree of RTA.
Chart 1: Dispersion of ASCII Characters by RTA (n = 8)

45

Table 21 summarizes the mapping between ASCII keyboard characters and the index trees of RTA (see Appendix B for details). The graph provides some indication of how good a job RTA is doing in dispersing i values to its forest of i-trees. It seems reasonable that a more even distribution between index trees would benefit the distributed tree of RTA. In fact, analysis of the actual index trees created by RTA when run on the test suit data shows that as n increases many trees are often left empty. This suggests that we can enhance the distributed tree of RTA by somehow doing a better job of evenly dispersing i values to the i-tree forest.

B.   EXPLANATION

Our Indexed Tree Approach (ITA) completely discards necklace classes and rotations as a mechanism to create a Huffman forest. Instead, as we read an input symbol S we use the first few bits of S (iBits) as a straightforward index into our Huffman forest. The remaining bits of S (jBits) are then used as a leaf value for the tree indexed by iBits. We make the following clarifying remarks:

- S is the concatenation of iBits with jBits.

- $|iBits| + |jBits| = n$.

- The integer representation of the unsigned value iBits is denoted by [iBits].

ITA proceeds as follows: We first read n-bit symbols from a source. We then divide each symbol into its respective iBits and jBits components. We put the iBits into one Huffman tree, and distribute the jBits into a forest of Huffman trees based upon the value of their associated iBits components. Finally, we write the Huffman codes for each iBits, jBits pair to the output file in the order they were originally discovered.

Clearly, ITA is a derivative of RTA. ITA creates a similar Huffman forest, and constructs similar ordered pairs of Huffman codes. It is, however, much more flexible than RTA. In RTA, a given value n *determines* the length of the r- and i- components of the algorithm. In ITA, the sum of |iBits| and |jBits| *determines* the value of n. Thus, there is only one way for RTA to compress a given file at a given n, while there are many ways for ITA to compress the same file using the same n. For example, if n = 12, ITA can be executed with the following (|iBits|, |jBits|) pairs: (1, 11), (2, 10), (3, 9), (4, 8), (5, 7), (6, 6), (7, 5), (8, 4), (9,3), (10, 2) and (11, 1).

C.   ALGORITHM

1. Build a static statistical model of the data as follows:

    a. Construct n + 1 empty frequency tables (indexed from 0 to n) where n>1 represents the length in bits of the symbols to read from the input stream.

    b. Read the next n-bit symbol S from the input stream.

    c. Divide S into its iBits and jBits components.

    d. If iBits does not exist in frequency table n, put iBits into frequency table n with frequency 1. Else, increment the frequency count of iBits in table n.

    e. If jBits does not exist in frequency table [iBits], put jBits into frequency table [iBits] with frequency 1. Else, increment the frequency count of jBits in table [iBits].

    f. While more symbols remain in the input stream, repeat step *a*.

47

2. Create a Huffman tree from each of the n + 1 frequency tables. The leaves of Huffman tree n represent iBits. The leaves of all other Huffman trees represent jBits.

3. Reset the input pointer to the beginning of the input stream.

4. Read the next n-bit symbol S from the input stream.

5. Divide S into its iBits and jBits components.

6. Write the Huffman code for iBits in Huffman tree n to the output stream.

7. Write the Huffman code for jBits in Huffman tree [iBits] to the output stream.

8. While more symbols remain in the input stream, repeat step 4.

D. INTERPRETATION OF RESULTS

We successfully implemented ITA in Java (see Appendix A) and collected empirical data (see Appendix B). In general, the compression performance of ITA is typically superior to that of standard Huffman encoding (and RTA) by a margin of one to three percent on text data. This difference is due to further decreases in the compressed file header size. ITA's performance is roughly equivalent to that of Huffman encoding on uncompressed bitmapped images. ITA is computationally more expensive than Huffman encoding, though like RTA, the difference is not apparent to the user. ITA does not suffer from the memory problems of RTA. In fact, it generally has a smaller memory footprint than does Huffman encoding.

Inspection of table 22 below (extracted from our empirical results, see appendix B) reveals that the performance gains made by ITA over Huffman and RTA are primarily attributable to further decreases in compressed file header size.

File	n	Optimal (|iBits|, |jBits|)	Huffman Header	RTA Header	ITA Header	Huffman Non-Header	RTA Non-Header	ITA Non-Header

Table 12: Header and Non-header Compression Results (in bytes)

In order to explain the decrease in header size from RTA to ITA we draw attention to the "optimal ($|iBits|$, $|jBits|$)" values displayed in column 3 of table 12. In most cases $|iBits|$ and $|jBits|$ are tightly centered on n/2. The reason for this goes back to the leaf lists discussed in chapter 4. The length and number of leaves in the leaf lists of a single iBits and jBits tree are given below.

	Leaf Length (bits)	Upper Bound on Number of Leafs
iBits tree	$|iBits|$	$2^{|iBits|}$
jBits tree	$|jBits|$	$2^{|jBits|}$

Table 13: Leaf Lists in a Single iBits and jBits Tree

An upper bound on the max leaf list size in bytes for a single iBits and jBits tree is found by summing the product of the leaf length and the number of leaves for each leaf list then dividing by 8. Table 14, below, shows how the upper bound for the size of the combined leaf lists of a single iBits and jBits tree change as i increases and j decreases.

n = 10 ($|iBits|$, $|jBits|$)	($|iBits| * 2^{|iBits|} + |jBits| * 2^{|jBits|}$) / 8
(1, 9)	576
(2, 8)	257
(3, 7)	115
(4, 6)	56
(5, 5)	40
(6, 4)	56
(7, 3)	115
(8, 2)	257
(9, 1)	576

Table 14: Sum of Leaf List Upper Bounds for a single iBits and jBits Tree

Table 14 illustrates how the ($|iBits|$, $|jBits|$) = (n/2, n/2) is a minimum of it's $f(|iBits|, |jBits|) = (|iBits| * 2^{|iBits|} + |jBits| * 2^{|jBits|}) / 8$. Thus ($|iBits|$, $|jBits|$) = (n/2, n/2)

produces a minimal size header for a hypothetical two-tree ITA. Since the actual ITA uses many jBits trees we would expect some repeated leaves in the header (just as in RTA). Thus, while it is possible for the ITA header to exceed the shown values, the table suggests optimal |iBits|, |jBits| pairs that fit well with the empirical data.

Naturally, (|iBits|, |jBits|) = (n/2, n/2) need not always be the exact optimal value. Indeed, this decomposition is only optimal in about 15% of our test cases. The most common optimal (|iBits|, |jBits|) pairs for n = 8, 12, 16, and 20 are (4, 4), (5, 7), (7, 9), and (9, 11) respectively. Thus, there are other factors at work besides simply header overhead. The most critical factor in overall compression results for ITA is the degree of similarity between ITA's distributed tree and an optimal Huffman tree constructed with the same data. If the distributed tree performs poorly, any gains made by reduced header overhead are quickly lost.

As mentioned earlier, ITA is more memory efficient than standard Huffman encoding. The reasons for this are similar to those behind the smaller header – it is simply cheaper to build many small Huffman trees than it is to build a single large one.

Since our performance gains over ITA are due to smaller header size, we conclude that ITA is no better at dispersing jBits than RTA was at dispersing i-values. Thus, although we are able to enhance the overall compression performance of RTA, we are unable to improve its distributed tree.

VI. CONCLUSIONS

A. SUMMARY OF MAIN RESULTS

We have presented two lossless compression techniques. Both techniques use a static statistical data model. Our first approach (RTA) involves binary necklace classes and multiple Huffman trees.

1. RTA compresses typical text data to within ±0.5% of standard Huffman encoding.

2. RTA is computationally more expensive than Huffman encoding, though not prohibitively so.

3. RTA is space- (memory-) inefficient to the point of being infeasible.

4. The non-header portion of a file compressed by RTA typically comes within 5% of the non-header portion of the same file compressed by standard Huffman encoding.

5. RTA has a more compact header than standard Huffman encoding. The difference between the headers increases as n increases. Thus, RTA performs best on large files with a high n.

Our second lossless compression approach (ITA) uses the same basic model as RTA, but abandons binary necklaces in lieu of a simpler and more efficient tree indexing mechanism.

6. ITA compresses typical text data one to three percent better than standard Huffman encoding. Compression of uncompressed bitmapped images is roughly equivalent to that of Huffman encoding.

7. ITA is computationally more expensive than Huffman encoding, though not prohibitively so.

8. ITA requires less memory than standard Huffman encoding.

9. The non-header portion of a file compressed by ITA typically comes within 5% of the non-header portion of the same file compressed by standard Huffman encoding.

10. ITA has a more compact header than standard Huffman encoding. The difference between the headers tends toward a maximum at values centered on n/2 and becomes more pronounced as n increases.

B.   FUTURE RESEARCH

This paper explores the use of binary necklace classes for lossless compression using a static statistical model. Our conclusions indicate that it is cheaper to pass header data for many small trees rather than a single large tree. Our approaches use one level of indirection (a single level of indirection equates to one thing pointing at many things) – a single tree pointing at a single forest. An interesting extension might be to have two or more levels of indirection. With two levels of indirection a single tree would point at a forest of trees, and each tree in the forest would then point at another forest. This

approach would greatly reduce the leaf length of each tree. The drawback is that the total number of trees would increase exponentially - thus greatly increasing the chance of overlapping leaves, something we found to be a drawback.

A mathematical topic closely related to necklace classes is that of Lyndon words. Lyndon words offer an opportunity to explore lossless compression using a dictionary-based model. Lyndon words exhibit some interesting properties, which may be applicable to data compression. Chapter 3 includes a short discussion on Lyndon words. Appendix A contains some preliminary java code, which generates an interesting subset of the Lyndon words.

APPENDIX B: SUMMARY OF EMPIRICAL DATA

To determine the performance of both RTA and ITA, we ran comparisons against standard Huffman encoding, using the Canterbury Corpus [19] and the well-known "Lenna" photograph [20]. The corpus is a suite of eleven text-based files, commonly used as an industry benchmark for testing lossless compression algorithms. This collection was developed in 1997 as an improved version of the older Calgary corpus. The files were chosen because their results on existing compression algorithms are "typical", and so it is hoped that they will be representative for new methods of compression as well. Lena is a Tagged Image File (TIF), which is an industry benchmark for image compression. The files that comprise The Canterbury Corpus are:

file	Abbrev	Category	Size in bytes
alice29.txt	text	English text	152089
asyoulik.txt	play	Shakespeare	125179
cp.html	html	HTML source	24603
fields.c	Csrc	C source	11150
grammar.lsp	list	LISP source	3721
kennedy.xls	Excl	Excel Spreadsheet	1029744
lcet10.txt	tech	Technical writing	426754
plrabn12.txt	poem	Poetry	481861
ptt5	fax	CCITT test set	513216
sum	SPRC	SPARC Executable	38240
xargs.1	man	GNU manual page	4227

Table 15: Canterbury Corpus Test Suite

The following graphs summarize the results of RTA, ITA, and Huffman encoding against the test suite files mentioned above. The title of the graph identifies the file and the tabular data represents the optimal compression for the given n. The ITA results of each graph represent the optimal combination of |iBits| + |jBits| = n for each file. The RTA results are do not extend beyond n = 24 due to the exponential memory requirements of this approach.
